Motivation

- We examine the value of improving knowledge of the economy, from perspective of welfare-maximizing monetary policymaker.
- Continuation of research program initiated by Goodfriend & King / Rotemberg & Woodford in 1997 NBER Macro Annual.
- Large literature on policy in stylized micro-founded models.
- Scarcity of research on policy under uncertainty.
Baseline Model Specification

- Habit persistence in consumption.
- Adjustment costs to changing investment.
- Variable capacity utilization.
- Staggered nominal wage and price contracts.
- Partial indexation to lagged inflation.
- Fundamental shocks: time prefs, leisure prefs, productivity, investment adj cost, govt spending.
  Non-fundamental: price markup, wage markup, equity prem.
  Monetary policy: inflation objective, idiosyncratic shock.
Preferences

Welfare:

\[ W_0(j) = E \sum_{t=0}^{\infty} \epsilon_t^B \beta^t V_t(j) \]

Period utility:

\[ V_t(j) = \frac{1}{1 - \sigma} (C(j)_t - \theta C(j)_{t-1})^{1-\sigma} - \frac{\epsilon_t^L}{1 + \chi} L_t(j)^{1+\chi} \]
Intermediate Goods Producers’ Technology

Intermediate goods output:

\[ Y_t(i) \leq \epsilon_t^A(U_t(i)K_{t-1}(i))^\alpha N_t(i)^{1-\alpha} - \Phi \]

Utilization costs:

\[ \Psi(U_t(i)) = \mu \frac{U_t(i)^{1+\psi^{-1}}}{1+\psi^{-1}} \]

Labor aggregator:

\[ N_t(i) = \left[ \int_0^1 L_t(i,j)^{1+\lambda_{w,t}} d\gamma \right]^{1+\lambda_{w,t}} \]
Intermediate Goods Producers’ Technology

Investment adjustment costs:

\[ K_t(i) = (1 - \delta)K_{t-1}(i) + [1 - S(\epsilon_t I_t(i)/I_{t-1}(i))]I_t(i) \]

\[ S(\epsilon_t I_t(i)/I_{t-1}(i)) = \zeta^{-1} \frac{1}{2} \left( \epsilon_t \frac{I_t(i)}{I_{t-1}(i)} - 1 \right)^2 \]
Final Goods Producers’ Technology

Aggregate final output (costlessly aggregated):

\[ Y_t = \left[ \int_0^1 Y_t(i)^{1+\lambda_{p,t}} di \right]^{1+\lambda_{p,t}} \]

Resource constraint:

\[ Y_t = C_t + G_t + I_t + \Psi(U_t)K_{t-1} \]
Estimated Monetary Policy Reaction Function

\[ r_t = r_i r_{t-1} \]
\[ + (1 - r_i) \left( \bar{\pi}_t + r_\pi (\pi_{t-1} - \bar{\pi}_t) + r_y \log(Y_{t-1}/Y^*_t) \right) \]
\[ + r_\Delta \pi (\pi_t - \pi_{t-1}) \]
\[ + r_\Delta y \left\{ \log(Y_t/Y^*_t) - \log(Y_{t-1}/Y^*_t) \right\} \]
\[ + \eta_t^R \]
Bayesian Estimation

• Log-linearize around steady state.

• Detrended data on consumption, investment, output, hours, real wage, inflation, fed funds rate.

• Sample period: 1955Q1 to 2001Q4.

• Priors based on existing estimates whenever possible.

• Obtain posterior distribution of the 31 parameters.

In the remainder of this section, we focus on characterizing the posterior distribution of the key structural parameters. Table 1 reports the posterior means and the 5% and 95% bounds for each of these parameters, while corresponding results for the parameters of the shock processes may be found in the appendix.

As depicted in Figure 1, the macroeconomic data are quite informative regarding the parameters related to price and wage determination. In light of recent micro-based evidence obtained by Bils and Klenow (2004) and Golosov and Lucas (2003), we specified a prior mean of 0.38 for the Calvo price-setting parameter $\xi_p$, corresponding to an average contract duration of about 1.5 quarters; we employed the same prior mean for the Calvo wage parameter $\xi_w$. In contrast, the posterior mean estimates for these two parameters imply an average contract duration of about five quarters, similar to the findings of CEE and SW.\(^{32}\) Furthermore, the posterior probability intervals of these estimates are relatively narrow, suggesting a fairly clear disconnect between the micro and macro evidence.

We impose relatively uninformative priors on the degree of price and wage indexation. The estimate of the degree of price indexation is near zero and relatively precisely estimated; in contrast, the degree of wage indexation is found to be substantial, but very imprecisely estimated (2004), and del Negro, Schorfheide, Smets, and Wouters (2004).

\(^{32}\)For comparison, Taylor (1993b), using a staggered wage model, estimates an average wage contract duration of about 3-1/2 quarters.
Figure 1: Estimated posterior distributions (red solid lines) and prior distributions (blue dashed) for the price and wage parameters.
Figure 2: Estimated posterior distributions (red solid lines) and prior distributions (blue dashed) for structural parameters.
Figure 8: Estimated posterior distributions (red solid lines) and prior distributions (blue dashed) for the parameters describing the shock processes.
Solving for Optimal Policy

The Ramsey policymaker’s objective is to maximize conditional expected household welfare at time zero, subject to the implementability constraints (namely, the behavioral equations of the private agents).

For illustrative purposes, consider the following case with a single endogenous variable $y_t$:

$$
\mathcal{L} = E \sum_{t=0}^{\infty} \beta^t \left\{ U(y_{t-1}, y_t) + \lambda_t H(y_{t-1}, y_t, y_{t+1}) \right\}
$$

where the Lagrangian involves the discount factor $\beta$, the utility function $U(\cdot)$, the behavioral equation $H(\cdot)$, and the Lagrange multiplier $\lambda_t$. 
The Policymaker’s First-Order Conditions

Differentiating with respect to $y_t$ yields the following FOC:

$$\frac{\partial \mathcal{L}}{\partial y_t} = E_0 \{ \beta^t U_2 (y_{t-1}, y_t) + \beta^{t+1} U_1 (y_t, y_{t+1})$$

$$+ \beta^{t-1} \lambda_{t-1} H_3 (y_{t-2}, y_{t-1}, y_t)$$

$$+ \beta^t \lambda_t H_2 (y_{t-1}, y_t, y_{t+1})$$

$$+ \beta^{t+1} \lambda_{t+1} H_1 (y_t, y_{t+1}, y_{t+2}) \} = 0$$

- Note that in the LQ setting, $U_1(\cdot)$ and $U_2(\cdot)$ are linear functions with constant coefficients while $H_i(\cdot)$ is simply a constant.
- More generally, however, these differentials are non-linear functions whose arguments vary over time.
## Optimal Steady State Inflation Rate and the Welfare Benefits from Zero to Ramsey Inflation

</tr>
</tbody>
</table>
Steady-State Lessons

- In the absence of wage dispersion, the optimal policy involves a relatively large steady-state deflation of -1.4 percent (a.r.), compared with an optimal rate of -0.8 in Khan et al. (2003), because the credit friction influences production and not just the consumption-leisure decision.

- Raising the magnitude of monopolistic distortions moves the optimal policy closer to Friedman’s rule, because monopolistic distortions magnify the consequences of the credit friction. (In Khan et al. (2003), greater monopolistic distortions diminish the monetary distortion and hence push the optimal policy closer to a zero steady-state inflation rate.)

- Wage dispersion is costly due to high elasticity of substitution between differentiated labor services (5% markup); thus, with no wage indexation, the optimal steady-state inflation is close to 0.
The Timeless Perspective

- Now we consider a logarithmic approximation of the model around the steady state of the Ramsey policy.

- This approximation may be viewed as representing the continuation of the Ramsey policy an arbitrarily long period after the initial period when the policy was implemented (cf. King & Wolman 1999; Khan, King & Wolman 2003).

- This policy is also referred to as the “timeless perspective” (cf. Giannoni & Woodford 2003; Benigno & Woodford 2003, 2004)
Figure 3: Impulse responses for one standard deviation positive shock to productivity; optimal policy (solid lines), empirical reaction function (dashed), RBC economy (dash-dotted lines).
Conditional vs. Unconditional Welfare

- Golden Rule vs. Modified Golden Rule
- Spurious benefits of increased uncertainty
- Ignores costs of building up capital stock (transition path)
- Technical Issue: conditional welfare should be evaluated before the start of time zero to reflect the implications of the squared shocks at time 0 in the reduced-form representation
Mean-Preserving Spreads

• When $x_t$ has a log-normal distribution, then the unconditional mean satisfies $E(x_t) = E(\log x_t) + 0.5Var(\log x_t)$.

• With i.i.d. disturbances, the mean-preserving spread (mps) is straightforward to implement; that is,

$$\log x_t = \log \bar{x} + \varepsilon_t - 0.5\sigma^2_{\varepsilon}$$

ensures that $E(x_t) = \bar{x}$ regardless of the innovation variance $\sigma^2_{\varepsilon}$.
Pitfalls in Preserving the Unconditional Mean

• In the case of persistent disturbances, care is needed to preserve the unconditional mean \( E(x_t) = \bar{x} \). For example, if one sets

\[
\log x_t = (1 - \rho) \log \bar{x} + \rho \log x_{t-1} + \varepsilon_t - 0.5\sigma^2_{\varepsilon}
\]

then

\[
E(\log x_t) = \log \bar{x} - \frac{\sigma^2_{\varepsilon}}{2(1 - \rho)}
\]

and

\[
Var(\log x_t) = \frac{\sigma^2_{\varepsilon}}{(1 - \rho^2)}
\]

so that \( E(x_t) = \bar{x} \exp \left[ \frac{-\rho \sigma^2_{\varepsilon}}{2(1 - \rho^2)} \right] \), which \textit{does not} equal \( \bar{x} \) unless \( \rho = 0 \).
Pitfalls in Preserving the Conditional Mean

• A correct way to preserve the unconditional mean of $x_t$ is as follows:

$$\log \tilde{x}_t = \rho \log \tilde{x}_{t-1} + \varepsilon_t$$

$$\log x_t = \log \tilde{x}_t + \log \bar{x} - \frac{0.5\sigma^2}{\rho^2}$$

• Nevertheless, this does not preserve the conditional mean $E_0(x_t)$, (which is essential for analyzing conditional welfare), because the conditional variance $\text{Var}_0(\log x_t) = \frac{\sigma^2}{\rho^2} \frac{(1 - \rho^2(t+1))}{(1 - \rho^2)}$. 
Preserving the Conditional Mean

- A correct way to preserve the conditional mean of $x_t$ is as follows:

$$\log \tilde{x}_t = \rho \log \tilde{x}_{t-1} + \varepsilon_t$$

$$mps_t = \rho^2 mps_{t-1} + 0.5\sigma^2_\varepsilon$$

$$\log x_t = \log \bar{x} + \log \tilde{x}_t - mps_t$$

Using this specification, $E\left( x_t \right) = \bar{x}$ for all $t \geq 0$. Furthermore,

$$mps_t \rightarrow \frac{0.5\sigma^2_\varepsilon}{\left(1-\rho^2\right)} \text{ as } t \rightarrow \infty,$$ as required to provide the appropriate correction for the unconditional mean as well.
optimal policy is associated with a markedly lower cost of business cycles, equivalent to about 2 percent of steady-state consumption. It should be noted that these welfare costs are an order of magnitude larger than in the results emphasized by Lucas (2003), mainly because staggered contracts induce substantial cross-sectional dispersion in relative prices and wages.\footnote{For related analysis and results, see Cho, Cooley, and Phaneuf (1997), Canzoneri, Cumby, and Diba (2004), and Paustian (2004).}

To gauge these welfare results more concretely, we note that U.S. personal consumption expenditures were about $28,000 per person in 2004; thus, switching from the empirical reaction function to the optimal policy would permanently raise welfare by about $160 per person, while eliminating all stochastic variation in the economy would generate a permanent welfare gain exceeding $700 per person. As we will see below, however, the magnitude of the welfare costs can be quite sensitive to the parameter values of the model as well as to the specification of the innovations and the determination of wages and prices.

### 4.3 Simple Policy Rules

We now consider the performance of simple policy rules with coefficients chosen to maximize welfare in the baseline model.\footnote{For analysis and discussion of the rationale for simple rules, see Taylor (1993a) and Williams (2003).} In particular, we examine rules with the following form:

\[
 r_t = r_t r_{t-1} + r_t \pi_t + r_t \omega_t, \tag{6}
\]

where the nominal interest rate \( r_t \) responds to the price inflation rate \( \pi_t \) and the nominal wage inflation rate \( \omega_t \) as well as to the lagged nominal interest rate. Rules of this type are operational in the sense of McCallum (1999), in the sense that the policy instrument is
Model Uncertainty

• Consider effects on policy of different forms of uncertainty.

• Parameter uncertainty: Assume different parameters, compare performance of a given rule to the optimal policy for that parameter set.

• Innovation uncertainty: Which shocks are efficient? Shocks could reflect measurement error, distortions.

• Specification uncertainty: Consider variations on the model. Here focus on different wage setting assumptions.
Figure 5: The distribution of welfare losses for the estimated posterior distribution. Top panel: Welfare losses relative to the steady state for the optimal policy tuned to each parameter draw (red line) and the benchmark wage inflation rule (dashed blue line) Bottom panel: Difference in welfare loss between the optimal and benchmark wage inflation rule.
Figure 6: Parameter uncertainty: price and wage setting. The difference between welfare under the benchmark wage inflation rule and the optimal policy is plotted as the dark red line. The two vertical lines indicate the 5 and 95 percent bounds from the posterior distributions.
Figure 7: Parameter uncertainty: other structural parameters. The difference between welfare under the benchmark wage inflation rule and the optimal policy is plotted as the dark red line. The two vertical lines indicate the 5 and 95 percent bounds from the posterior distributions.

policy rule performs well, although the difference between it and the rules that respond to price inflation is much smaller than in the baseline model.

6 Innovation Uncertainty

We now consider alternative assumptions regarding the set of shocks in the model. In computing welfare, we have had to take a stand on each shock as to whether it reflects shifts in fundamentals, the effects of distortions, or measurement error. In particular, we have assumed that the wage and price shocks and the shocks to the external finance premium are distortionary, while the remaining shocks reflect shifts in fundamentals. We now revisit these assumptions and evaluate the performance of the various monetary policies under alternative assumptions regarding the nature of innovations.

The baseline model is admittedly profligate in specifying shocks. In particular, the external finance premium has a large estimated variance and may be important for welfare according to the model, but arguably lacks microfoundations. Importantly, we have assumed that this shock does not affect fundamentals, but instead represents inefficient fluctuations in an external finance premium or a type of “animal spirits” that monetary should counteract. In contrast, we have assumed that investment adjustment costs shocks reflect fundamentals and their effects should be accommodated. We therefore consider an alternative model spec-

In a previous version of this paper, we estimated an alternative model that included no external finance premium shocks. Estimates of most model parameters were nearly identical to the baseline estimates. Exceptions included the estimate of $\zeta$, which fell, implying significantly higher costs of adjusting investment, and the investment adjustment cost shock became more variable and less persistent. The effects on welfare of this specification were modest.
Monetary Frictions

- We include money in the utility function and a nominal interest rate cost channel
- We then reestimated the model (the benchmark estimates changed little)
- These changes introduce a cost to fluctuating nominal interest rates
- The optimal inflation rate is slightly negative
- The performance of the benchmark rule suffers because it generates too much interest rate variability

to rate of price inflation. This modification to the model reduces the effects of fluctuations in wage inflation on wage dispersion and thereby welfare. Table 4 reports the results from this specification for four specifications of monetary policy. Not surprisingly, the consumption-equivalent loss in conditional welfare under the optimal policy is somewhat smaller than in the baseline model.

The relative performance of the benchmark wage inflation rule, however, is considerably worse under this form of wage indexation, and is dominated by the rule that responds only to price inflation. Under the benchmark wage inflation policy rule, the consumption-equivalent loss in conditional welfare is 0.6 percentage points larger than under the optimal policy and 0.3 percentage points higher than under the benchmark price inflation rule. In fact, with this specification of wage indexation, the benchmark wage inflation policy rule does slightly worse than the estimated policy rule. Evidently, the result that a simple policy rule designed to maximum welfare should respond exclusively to wage inflation is not robust to changes in the model of wage determination, even to this seemingly innocuous change in the model specification.

We now consider a more substantive change in the specification of wage and price determination, and assume that contracts have fixed duration as in Taylor (1980); see also Chari, Kehoe, and McGrattan (2000). Compared with the baseline specification of Calvo-style

---

56 We estimated a version of the baseline model where wage indexation depends on a combination of past price and wage inflation. We found that the weight is primarily on past price inflation, providing support for the baseline model specification. Nonetheless, one may not be convinced by this finding and remained concerned about uncertainty regarding the form of wage indexation.

57 As explained below, we have not formally estimated this alternative specification. The empirical performance of the model may be sensitive to which type of nominal rigidity is assumed; see Chari, Kehoe, and McGrattan (2000), Kiley (2002), and Guerrieri (2001).
Conclusion

• In benchmark specification, we find that a simple wage inflation rule is nearly optimal.

• Parameter uncertainty, as summarized by posterior distribution or sampling variation, is generally unimportant for policy.

• Model specification is crucial for monetary policy.

• Our analysis highlights the need for further research on the functioning of labor markets.
Monetary Policy Under Uncertainty in Micro-Founded Macroeconometric Models*

Abstract

We use a micro-founded macroeconometric modeling framework to investigate the design of monetary policy when the central bank faces uncertainty about the true structure of the economy. We apply Bayesian methods to estimate the parameters of the baseline specification using postwar U.S. data, and then determine the policy under commitment that maximizes household welfare. We find that the performance of the optimal policy is closely matched by a simple operational rule that focuses solely on stabilizing nominal wage inflation. Furthermore, this simple wage stabilization rule is remarkably robust to uncertainty about the model parameters and to various assumptions regarding the nature and incidence of the innovations. However, the characteristics of optimal policy are very sensitive to the specification of the wage contracting mechanism, thereby highlighting the importance of additional research regarding the structure of labor markets and wage determination.

Uncertainty is not just an important feature of the monetary policy landscape; it is the defining characteristic of that landscape.

Alan Greenspan (2003)

1 Introduction

Eight years ago, two Macroeconomics Annual papers—Goodfriend and King (1997) and Rotemberg and Woodford (1997)—played a central role in stimulating a burgeoning research program regarding the monetary policy implications of macroeconomic models with explicit microeconomic foundations.1 This research program incorporates two crucial elements compared with more traditional monetary policy analysis. First, reflecting the influence of the Lucas (1976) critique, the emphasis on explicit microeconomic foundations is intended to ensure that the resulting structural equations are reasonably invariant to the choice of monetary policy. Second, this research follows the standard public finance approach of determining the policy regime that maximizes household welfare and then evaluating the performance of alternative policies relative to this benchmark.

After initially focusing on small stylized models, this line of research has subsequently proceeded to analyze micro-founded macroeconometric models that incorporate an expanded set of nominal and real rigidities and hence can be matched more closely to observed aggregate data. For example, Christiano, Eichenbaum, and Evans (2005) (henceforth CEE) specified a dynamic general equilibrium model with a number of distinct structural features: staggered wage and price setting with partial indexation; habit persistence in consumption; endogenous capital accumulation with higher-order adjustment costs; and variable capacity utilization.2 Smets and Wouters (2003a) (henceforth SW) later applied full-information

---

1 Other early examples include Levin (1989), King and Wolman (1999), McCallum and Nelson (1999), and Rotemberg and Woodford (1999). For a thorough presentation of this approach as well as a comprehensive bibliography, see Woodford (2003).

2 Christiano, Eichenbaum, and Evans (2005) also documented the importance of these structural features in generating a model-implied response to a monetary policy shock consistent with that of an identified vector autoregression (VAR). More recently, Altig, Christiano, Eichenbaum, and Linde (2004) have extended the model to incorporate firm-specific capital accumulation and have analyzed its behavior in response to productivity shocks, while Christiano, Motto, and Rostagno (2004) incorporate a banking system and capital market frictions in their study of the Great Depression.
Bayesian methods to estimate essentially the same specification (augmented by a larger set of structural disturbances), and found that the model is competitive with an unrestricted Bayesian VAR in terms of goodness-of-fit and out-of-sample forecasting performance.\(^3\)

In this paper, we investigate the design of monetary policy when the central bank faces uncertainty regarding the true structure of the economy. Of course, a long-established literature has considered this topic using traditional structural macroeconomic models, building on the seminal work of Brainard (1967).\(^4\) Nevertheless, recent analysis of small stylized micro-founded models has demonstrated that the implications of uncertainty can be markedly different when the policymaker’s goal is to maximize household welfare, because the welfare function itself depends on the specification and parameter values of the model.\(^5\)

By utilizing a micro-founded macroeconometric modeling framework, we can examine the policy implications of several aspects of uncertainty that may be more difficult to consider in a small stylized model. First, by applying Bayesian methods, we can use the posterior distribution of the model parameters to determine whether simple rules that perform well in the baseline economy are robust to *parameter uncertainty*, that is, to the range of parameter values that are reasonably consistent with the observed data. Second, we can gauge the degree of *innovation uncertainty* by evaluating the extent to which the policy conclusions are sensitive to alternative assumptions regarding the nature and incidence of the structural shocks to the model. Finally, we can explore the implications of *specification uncertainty* by changing specific features of the model such as the role of money balances or the structure of nominal contracts.\(^6\)

As the baseline specification for our analysis, we consider a micro-founded macroecono-
metric model similar to those studied by CEE and SW. Applying a Bayesian procedure to estimate this model with postwar U.S. data, we set the baseline values of the model parameters using the mean of the posterior distribution. We employ Lagrangian methods to determine the optimal policy under commitment in the baseline economy. Finally, we use second-order perturbation to solve the model and compute the level of welfare under the optimal policy as well as for alternative simple rules.\footnote{The optimal policy regime and optimized simple rules have previously been studied in micro-founded macroeconometric models by Onatski and N. Williams (2004), Levin and Lopez-Salido (2004), Laforte (2003), and Schmitt-Grohé and Uribe (2004).}

We find that the welfare outcome under optimal policy is closely matched by a simple interest rate rule that responds solely to nominal wage inflation and the lagged interest rate.\footnote{While we focus on simple interest rate rules in this paper, an alternative approach is to specify a simplified objective function for the central bank, as in the literature on flexible inflation targeting; see Svensson and Woodford (2004) and Giannoni and Woodford (2004). Although not reported here, our preliminary analysis suggests that stabilizing a wage inflation objective may also perform well in terms of welfare.} Because this rule only involves observable variables and does not require a measure of the output gap, the natural rate of interest, or forecasts of variables, the rule can be implemented without assuming that the policymaker knows the correct specification of the model or the true values of the model parameters.

The near-optimality of the simple wage stabilization rule is directly attributable to the overriding importance of nominal wage inertia in determining the welfare costs of aggregate fluctuations in the baseline economy. This inertia reflects the relatively long duration of nominal wage contracts as well as the nearly-uniform degree of indexation to lagged inflation. Furthermore, under our baseline specification of Calvo-style contracts with an exogenous probability of reoptimization, many wage contracts remain in effect much longer than the one-year average duration. Thus, as emphasized by Erceg, Henderson, and Levin (2000), stabilizing aggregate wage inflation helps alleviate the degree of cross-sectional dispersion in real wages and thereby minimizes the associated inefficiencies in employment of differentiated labor services and in the allocation of leisure across households.

The simple wage stabilization rule is remarkably robust to parameter uncertainty and
innovation uncertainty and to some modifications of the baseline model specification. For example, this rule yields near-optimal performance throughout the empirically relevant range of values of the model parameters, a finding consistent with our earlier work regarding the relatively minor importance of this type of uncertainty.\(^9\) The performance of the wage stabilization rule is also relatively insensitive to various assumptions regarding the nature and incidence of the innovations and to augmenting the model to incorporate monetary frictions.

Nevertheless, the policy implications can be quite sensitive to alternative specifications of the wage contracting mechanism. In particular, the welfare costs of nominal wage variability are much smaller when wages are determined by Taylor-style contracts with the same average duration as in our baseline specification of Calvo-style contracts.\(^10\) Thus, the simple wage stabilization rule is no longer nearly optimal and better welfare outcomes are provided by other simple rules that respond to price inflation or real economic variables. Of course, as Hall (this volume) emphasizes, neither Calvo-style nor Taylor-style contracts may provide the ideal microeconomic foundations for the determination of nominal wages and employment. Thus, these results should be interpreted as highlighting the extent to which additional research regarding the structure of labor markets is likely to have substantial benefits for the design of monetary stabilization policy.

The remainder of this paper is organized as follows. Section 2 provides an overview of the baseline model specification. Section 3 briefly describes the estimation procedure and the posterior distribution of the model parameters. Section 4 characterizes the optimal policy in the baseline economy and compares the performance of alternative simple rules. Sections 5 and 6 analyze the implications of parameter uncertainty and innovation uncertainty, respectively. Section 7 considers several types of specification uncertainty. Section 8 concludes. The appendices contain some additional derivations and results.

2 The Model

As in CEE and SW, our baseline model incorporates a number of mechanisms that can induce intrinsic persistence in the propagation of shocks, including habit persistence in consumption, costs of adjustment for investment and capacity utilization, and staggered nominal wage and price contracts with partial indexation. The model also includes a number of exogenous disturbances (assumed to be mutually uncorrelated) that account for the stochastic variation in the observed data utilized in our estimation procedure.

2.1 Household Preferences

The economy has a continuum of infinitely-lived households. The conditional welfare of a given household \( h \in [0, 1] \) at a given time \( t \) is defined as the discounted sum of expected period utility:

\[
W_t(h) = E_t \sum_{j=0}^{\infty} \beta_t^{j+1} V_{t+j}(h),
\]

where the subjective discount factor is \( \beta_t = \beta Z_t^b \) and we define \( \beta_t^{j+1} = \prod_{s=0}^{j} \beta_t^{s+1} \). Thus, the steady-state subjective discount factor is given by the parameter \( 0 < \beta < 1 \), while stochastic variation in the rate of time preference is induced by the exogenous disturbance \( Z_t^b \); we assume that the logarithm of this disturbance follows an AR(1) process.

The period utility function of a given household \( h \) at time \( t \) is specified as follows:

\[
V_t(h) = \frac{(C_t(h) - \theta C_{t-1}(h))^{1-\sigma}}{1-\sigma} - \frac{Z_t^L(L_t(h))^{1+\chi}}{1+\chi} + \mu_0 \frac{Z_t^m(M_t(h))^{1-\kappa}}{1-\kappa},
\]

where \( C_t(h) \) denotes the household’s total consumption, \( L_t(h) \) denotes its labor hours, and \( M_t(h) \) denotes its real cash balances.\(^{11}\) The preference parameters \( \sigma, \chi, \kappa, \) and \( \mu_0 \) are strictly positive, while \( \theta \) lies in the unit interval. The exogenous disturbance \( Z_t^L \) induces stochastic variation in household preferences for leisure relative to consumption, and \( Z_t^m \) is an exogenous shock to money demand; the logarithm of each shock is assumed to follow an AR(1) process.

---

\(^{11}\)We interpret \( M_t \) as broad money and assume that households invest the remainder of their assets \( A_t - M_t \) with a financial intermediary earning the nominal interest rate \( R_t \).
Habit persistence in consumption is an important but somewhat controversial feature of this specification. In particular, for positive values of $\theta$, the household's lagged consumption effectively serves as a reference value in determining the period utility generated by current consumption.\textsuperscript{12} Recent empirical analysis of aggregate data has obtained substantial evidence of habit persistence; for example, CEE emphasize its role explaining the hump-shaped behavior of aggregate consumption in response to a monetary policy shock. Nevertheless, it should be noted that micro-level studies have occasionally obtained results that directly conflict with the macro evidence.\textsuperscript{13}

Of course, the curvature parameters of the utility function also remain quite controversial. Some studies have argue that $\sigma$ is around unity, while others find much larger values.\textsuperscript{14} Furthermore, microeconometric studies have typically obtained estimates of $\chi$ that are significantly greater than unity, whereas some macroeconomists have argued that the aggregate data is consistent with a near-zero value of $\chi$, corresponding to a very high intertemporal elasticity of leisure for the representative household.\textsuperscript{15}

Finally, while this specification allows real money balances to directly influence household utility, most of our analysis will focus on the "cashless economy" emphasized by Woodford (2003) and others; this economy corresponds to the limiting case in which $\mu_0$ becomes arbitrarily small. Later in the paper, however, we will revisit this issue and examine the policy implications of incorporating a non-trivial role for money into the model.

\textsuperscript{12}Some authors have considered an alternative specification, referred to as "external habit persistence," in which the lagged value of aggregate consumption serves as the reference value for each individual household. In the absence of offsetting taxes, this formulation poses an externality that distorts the steady state; thus, given our emphasis on the stabilization role of monetary policy, in this paper we focus exclusively on the "internal habit" specification given in the text.

\textsuperscript{13}For example, see the contrast between the conclusions of Fuhrer (2000) and Dynan (2000).

\textsuperscript{14}See Guvenen (2005) for a recent survey of the literature and an attempt to reconcile the differences in published estimates.

\textsuperscript{15}See Huang and Liu (2004) for a summary of recent evidence regarding the intertemporal elasticity of labor supply at the intensive and extensive margins.
2.2 Production and Prices

The final composite good—used for both consumption and investment—is obtained by bundling together a continuum of differentiated intermediate goods using a Dixit-Stiglitz aggregator function. As in SW, we allow the elasticity of substitution between different goods to exhibit exogenous temporal variation; that is, \( \lambda_p^p = Z_t^p \lambda_p \). The parameter \( \lambda_p > 0 \) determines the steady-state markup rate, while the exogenous disturbance \( Z_t^p \) (assumed to have an i.i.d. log-normal distribution) shifts the desired markup at each point in time. Given this specification, a given firm \( i \in [0, 1] \), as the sole producer of intermediate good \( i \), faces a downward-sloping demand curve, and its elasticity of demand \( -(1 + \lambda_p^p)/\lambda_p^p \) is invariant to the firm’s level of production.\(^{16}\)

Interestingly, the steady-state markup parameter \( \lambda_p \) does not influence the first-order dynamics of the model economy and hence cannot be estimated using the methods employed in this paper. Nevertheless, this parameter does affect the second-order properties of the model, including the welfare performance of monetary policy rules. In light of the available evidence from disaggregated data, we set \( \lambda_p = 0.20 \) in the baseline version of the model, and then consider alternative values from 0.05 to 0.50.\(^{17}\)

Every intermediate-goods producer has an identical production function that determines the gross output of good \( i \) as a Cobb-Douglas function of the firm’s employment of labor services \( N_t(i) \), its rental of capital services \( \tilde{K}_t(i) \), and the exogenous economy-wide productivity factor \( A_t \):

\[
Y_t(i) = A_t \tilde{K}_t(i)^{\alpha} N_t(i)^{1-\alpha} - \Phi,
\]

where the parameter \( \alpha \) represents the share of capital in gross output, and we assume that the logarithm of the productivity factor follows an AR(1) process. As in CEE and SW, every

\(^{16}\)Kimball (1995) proposed a more general form of aggregator function that allows for quasi-kinked demand curves, and several recent empirical studies have analyzed its first-order implications; cf. Eichenbaum and Fisher (2004), Altig, Christiano, Eichenbaum, and Linde (2004), and Coenen and Levin (2004). However, higher-order approximations of the Kimball specification have not yet been considered, and remain well beyond the scope of the present analysis.

\(^{17}\)For empirical analysis of demand elasticities and markups, see Shapiro (1987), Basu (1996), and Basu and Fernald (1997).
firm hires its capital and labor services on competitive economy-wide markets and hence has
the same marginal cost of production.

The firm’s net output $Y_t(i)$ reflects the presence of the fixed overhead cost $\Phi$. This
fixed cost induces locally increasing returns to scale for each individual firm, and generates
procyclical total factor productivity at the aggregate level. Thus, inferences about the value
of $\Phi$ can be made using both micro-level and macro-level data.

In the baseline version of the model, we assume that prices are determined by Calvo-
style nominal contracts with partial indexation.\textsuperscript{18} In particular, every firm faces a constant
probability $1 - \xi_p$ of reoptimizing its price contract in any given period, where $\xi_p \in [0, 1]$;
thus, price contracts have an average duration $1/(1 - \xi_p)$. Whenever the contract is not
reoptimized, the firm’s price is automatically adjusted by the lagged rate of inflation raised
to the power $\gamma_p \in [0, 1]$.

This specification of price-setting behavior provides formal underpinnings for the hybrid
New Keynesian Phillips curve.\textsuperscript{19} In particular, the indexation parameter $\gamma_p$ determines the
relative weight on the “backward-looking” vs. “forward-looking” terms in the hybrid Phillips
curve. While the magnitude of these weights is subject to ongoing controversy, recent analysis
of aggregate data seems to be largely consistent with the available microeconomic evidence
indicating that indexation is not a typical characteristic of price adjustment.\textsuperscript{20}

Under the assumption that all firms have identical marginal cost, responsiveness of in-
flation to current marginal cost is determined solely by the parameter $\xi_p$. Thus, as in SW,
the estimated value of $\xi_p$ tends to imply a relatively long average duration of price contracts
that is inconsistent with recent microeconomic evidence.\textsuperscript{21} Several recent studies have shown
that incorporating additional real rigidities—such as quasi-kinked demand and firm-specific

\begin{itemize}
\item \textsuperscript{18}See Yun (1996) and Woodford (2003) for analysis of the microeconomic underpinnings of the contract
structure introduced by Calvo (1983).
\item \textsuperscript{19}See Clarida, Gali, and Gertler (1999) and Woodford (2003).
\item \textsuperscript{20}For aggregate evidence on the degree of intrinsic inflation persistence, see Gali, Gertler, and Lopez-Salido
(2001) and Levin and Piger (2004). For a recent discussion of the microeconomic evidence, see Angeloni,
\item \textsuperscript{21}See Bils and Klenow (2004), Klenow and Kryvtsov (2004), and Dhyne, Alvarez, Bihan, Veronese, Dias,
Hoffmann, Jonker, Linemann, Rumler, and Vilmunen (2005).
\end{itemize}
capital—yields more plausible estimates of the degree of nominal rigidity. Nevertheless, analyzing the second-order implications of these mechanisms poses some technical challenges that remain to be addressed in future work.

2.3 Investment and Capacity Utilization

Households own the entire stock of physical capital $K_t$. Capital accumulation is subject to adjustment costs that are assumed to be proportional to the squared growth rate of investment, rather than the more traditional formulation involving the squared level of investment. As emphasized by CEE, this specification of adjustment costs can generate a hump-shaped response of aggregate investment to a monetary policy shock, consistent with the implications of an identified vector autoregression. While the formal microeconomic foundations of this mechanism were initially opaque, Basu and Kimball (2003) have subsequently shown that very similar implications can be obtained in a framework with planning delays in investment.

Thus, the capital stock owned by a given household $h \in [0, 1]$ evolves as follows:

$$K_t(h) = (1 - \delta)K_{t-1}(h) + \left[1 - \zeta^{-1} \frac{1}{2} \left(Z_I^t \frac{I_t(h)}{I_{t-1}(h)} - 1\right)^2\right]I_t(h),$$

(4)

where $K_t(h)$ denotes the household’s beginning-of-period capital stock and $I_t(h)$ denotes the gross investment during period $t$. The depreciation rate is given by $\delta$, and the parameter $\zeta$ gauges the magnitude of investment adjustment costs. Finally, the exogenous disturbance $Z_I^t$ acts as an economy-wide shock to investment demand; its logarithm follows an AR(1) process.

In each period, the aggregate flow of capital services $\bar{K}_t$ to the intermediate-goods sector is defined as the capacity utilization rate $U_t$ multiplied by the predetermined level of the physical capital stock, $K_{t-1}$. The capacity utilization rate can vary from its steady-state.

---

23 This adjustment cost specification incorporates the basic properties assumed by CEE and SW, who were only concerned with characterizing the steady state and log-linear properties of the model. By using an explicit definition of the adjustment cost function, we are able to analyze the second-order approximation of the model economy.
value of unity, but such variations are associated with a real resource cost. In particular, we specify the resource cost $\Psi_t(h)$ incurred by a given household $h$ as a CES function of its capacity utilization $U_t(h)$:

$$\Psi_t(h) = \mu \frac{U_t(h)^{1+\psi^{-1}} - 1}{1 + \psi^{-1}}.$$  \hspace{1cm} (5)

where $\psi \geq 0$ and $\mu > 0$.\textsuperscript{24}

As emphasized by CEE, variable capacity utilization can effectively enhance the short-term flexibility of the economy in response to aggregate shocks. Nevertheless, the magnitude of the utilization cost parameter $\psi$ is currently subject to a great deal of uncertainty, due to the scarcity of microeconomic evidence as well as conflicting results from recent macroeconometric analysis. For example, CEE find that variations in capacity utilization play an important role in explaining the sluggish response of inflation to a monetary policy shock, whereas the results of Altig, Christiano, Eichenbaum, and Linde (2004) suggest that the aggregate effects of a technology shock are only consistent with relatively limited variations in capacity utilization.

Finally, following SW, we include an “external finance premium” shock $Z^q_t$ (assumed to have an i.i.d. log-normal distribution) which acts as a wedge between the risk-free real interest rate and the required expected rate of return on physical capital. Recent analysis of firm-level data has obtained precise estimates of the magnitude and cyclical behavior of the external finance premium; cf. Levin, Natalucci, and Zakrajsek (2004). However, further theoretical and empirical research is clearly needed to elucidate the underpinnings and implications of this mechanism.

### 2.4 Employment and Wages

Households provide a continuum of differentiated labor services, which are bundled together using a Dixit-Stiglitz aggregator function and then rented to the intermediate sector. As in SW, we allow the elasticity of substitution between different types of labor services to ex-
hibit exogenous temporal variation; that is, $\lambda^w_t = Z^w_t \lambda^w$. The parameter $\lambda^w > 0$ determines the steady-state markup of real wages over the marginal rate of substitution between consumption and leisure. The exogenous disturbance $Z^w_t$ (assumed to have an i.i.d. log-normal distribution) shifts the desired wage markup at each point in time. Given this specification, a given household $h \in [0, 1]$, as the sole provider of the labor service of type $h$, faces a downward-sloping labor demand curve with elasticity $-(1 + \lambda^w_t)/\lambda^w_t$.

In the baseline version of the model, we assume that wages are determined by Calvo-style nominal contracts with partial indexation. In particular, each household faces a constant probability $1 - \xi^w$ of reoptimizing its wage contract in any given period, where $\xi^w \in [0, 1]$. Whenever the contract is not reoptimized, the household’s wage is automatically adjusted by the lagged rate of price inflation raised to the power $\gamma^w \in [0, 1]$.

The steady-state markup parameter $\lambda^w$ and the contract wage parameter $\xi^w$ cannot be independently identified from the log-linear dynamics of the model. Given the scarcity of disaggregated evidence on these two parameters, we proceed by calibrating $\lambda^w = 0.20$ (the same baseline value as for $\lambda^p$) and estimating the value of $\xi^w$.\(^{25}\) We will then gauge the policy and welfare implications of alternative combinations of these two parameters that yield the same first-order behavior of the model.

Because the wage-setting mechanism has crucial implications for the design of optimal monetary policy, we will also consider two modifications to the baseline specification, namely, indexation of wages to lagged wage inflation instead of lagged price inflation, and the use of fixed-duration “Taylor-style” wage contracts instead of Calvo-style contracts. As we will see, these alternative specifications yield significantly different implications for monetary policy and welfare.

\(^{25}\)Taylor (1999b) provides an overview of the evidence on nominal wage inertia. For analysis of the elasticity of demand for differentiated labor services, see Griffin (1996a), Griffin (1996b).
2.5 Fiscal and Monetary Policy

We assume that government spending is exogenously determined and exhibits persistent variations; in particular, its logarithm follows an AR(1) process. As evident from the previous discussion, government spending has no direct effects on either utility (through purchases of public goods) or production (perhaps via a stock of public capital); consideration of these channels, as well as automatic fiscal stabilizers, is deferred to future research.

Furthermore, we assume that the government offsets the steady-state effects of monopolistic distortions by enacting the appropriate magnitude of production and employment subsidies which are financed via a constant level of lump-sum taxes. Thus, the deterministic steady state is Pareto-optimal in the baseline model with a zero inflation rate. Under these assumptions, we can focus our analysis on the stabilization task of monetary policy, abstracting from the complications that would arise if the central bank also played a role in trying to offset the effects of steady-state distortions.\textsuperscript{26}

In estimating the model, we utilize a fairly simple monetary policy rule in which the short-term nominal interest rate responds to the lagged interest rate as well as to deviations of aggregate price inflation from target and of actual output from the level that would prevail in the absence of nominal inertia. This specification includes two additional exogenous shocks, namely, persistent AR(1) shifts in the inflation objective and transitory white-noise shocks to the current policy rate. In our normative analysis, of course, we consider the full Ramsey policy as well as alternative specifications of simple policy rules, and we assume that monetary policy does not exhibit any exogenous stochastic variation.

3 Model Estimation

We employ Bayesian methods to estimate the log-linearized version of the model, using quarterly U.S. data over the period 1955:1 through 2001:4.\textsuperscript{27} In particular, we treat seven

\textsuperscript{26} For analysis of optimal policy in economies with steady-state distortions, see Benigno and Woodford (2004) and Schmitt-Grohe and Uribe (this volume).

\textsuperscript{27} A detailed description of the log-linearized model is provided in Appendix B.
aggregate variables as directly observed: real consumption, real investment, real GDP, real wages, total hours, GDP price inflation, and the federal funds rate.\textsuperscript{28} Because the rest of the model variables (such as the capital stock) are treated as unobserved, we use the Kalman filter in computing the likelihood function of the model.

As widely recognized in earlier work, certain structural parameters are not well-identified from the cyclical dynamics of the data. Therefore, we use long-term historical averages to specify the values of these parameters: the capital share parameter $\alpha = 0.36$; the discount factor $\beta = 0.99$ (corresponding to a steady-state real interest rate of about 4 percent); and the depreciation parameter $\delta = 0.025$ (corresponding to an annual rate of about 10 percent).

Similarly, we calibrate the output shares of consumption, investment, and government spending at $c_y = \bar{C}/\bar{Y} = 0.56$, $i_y = 0.24$, and $g_y = 0.20$, respectively.\textsuperscript{29} Finally, we set the wage and price markup parameters $\lambda^w = \lambda^p = 0.2$; in the following section, we will consider the implications of alternative values for these two parameters.

We formulate independent prior densities for each of the other 31 parameters of the model, namely, ten parameters related to preferences and technology, five coefficients of the empirical interest rate reaction function, and sixteen parameters of the data-generating processes for the disturbances. Overall, our prior is consistent with the previous literature and is relatively uninformative for most of the parameters; details are given in the appendix.\textsuperscript{30} Given these priors, we characterize the posterior distribution using a Metropolis-Hastings Markov chain Monte Carlo (MCMC) algorithm. Our estimation methodology is broadly similar to that of Lubik and Schorfheide (2005); further details are provided in the appendix.\textsuperscript{31}

\textsuperscript{28}We use the same dataset as in Altig, Christiano, Eichenbaum, and Linde (2004), obtained from Marty Eichenbaum’s web page. The real wage is constructed as non-farm wage rate adjusted by the GDP price deflator, while total hours are measured for the non-farm business sector. The inflation rate and interest rate are demeaned and converted to quarterly rates; the other five variables are measured in logarithmic deviations from linear trends, in percentage points.

\textsuperscript{29}The mean ratio of net exports to GDP was zero to two decimal points over our sample.

\textsuperscript{30}In specifying these priors, we have drawn heavily on Smets and Wouters (2003a), (Smets and Wouters 2003b), Christiano, Eichenbaum, and Evans (2005), Altig, Christiano, Eichenbaum, and Linde (2004), and Onatski and N. Williams (2004).

\textsuperscript{31}Since the work of Schorfheide (2000) and especially after the original Smets and Wouters (2003a) paper there have been a number of papers using Bayesian methods for models similar to ours; examples include Del Negro and Schorfheide (2004), Rabanal and Rubio-Ramirez (2003), Laforte (2003), Onatski and N. Williams

In the remainder of this section, we focus on characterizing the posterior distribution of the key structural parameters. Table 1 reports the posterior means and the 5% and 95% bounds for each of these parameters, while corresponding results for the parameters of the shock processes may be found in the appendix.

As depicted in Figure 1, the macroeconomic data are quite informative regarding the parameters related to price and wage determination. In light of recent micro-based evidence obtained by Bils and Klenow (2004) and Golosov and Lucas (2003), we specified a prior mean of 0.38 for the Calvo price-setting parameter $\xi_p$, corresponding to an average contract duration of about 1.5 quarters; we employed the same prior mean for the Calvo wage parameter $\xi_w$. In contrast, the posterior mean estimates for these two parameters imply an average contract duration of about five quarters, similar to the findings of CEE and SW.\textsuperscript{32} Furthermore, the posterior probability intervals of these estimates are relatively narrow, suggesting a fairly clear disconnect between the micro and macro evidence.

We impose relatively uninformative priors on the degree of price and wage indexation. The estimate of the degree of price indexation is near zero and relatively precisely estimated; in contrast, the degree of wage indexation is found to be substantial, but very imprecisely

\textsuperscript{32}For comparison, Taylor (1993b), using a staggered wage model, estimates an average wage contract duration of about 3-1/2 quarters.
Figure 1: Estimated posterior distributions (red solid lines) and prior distributions (blue dashed) for the price and wage parameters.
estimated. The lack of price indexation differs from SW, but is consistent with the findings of Ireland (2001) and Edge, Laubach, and J. Williams (2003).

The macroeconomic data are somewhat less informative regarding other structural parameters. Figure 2 repeats the previous figure for the structural parameters not related to price and wage determination. Overall, the resulting estimates are consistent with estimates from the literature. Except for the parameters determining capacity utilization costs and habit persistence, the posteriors do not differ greatly from the respective priors. The finding of a relatively tight posterior distribution for the capacity utilization cost parameter occurs despite the imposition of a relatively loose prior and contrasts with the wide dispersion of estimates of this parameter in the literature.

One structural parameter that deserves further discussion is the returns to scale in production, $\phi$. We chose a relatively tight prior centered on 1.08 for this parameter, based on the estimates of Basu (1996) and Basu and Fernald (1997), who find fixed costs of between 3 and 10 percent. Our resulting mean estimate is 1.09. By comparison, when we imposed an uninformative prior, the mode estimate exceeded 2, a result consistent with the findings of SW, but contrary to the micro evidence. Despite this difference in point estimates, in fact the data were not terribly informative about this parameter, as seen in the figure. Interestingly, imposing our prior on $\phi$ resulted in a small estimate of investment adjustment costs. Our estimate of investment adjustment costs are noticeably lower than SW, but more in line with those reported by ACEL.

For the monetary policy reaction function, we obtain the following estimation results:

$$r_t = 0.84 \ r_{t-1} + 0.16 \left[ 2.7 \ (\pi_{t-1} - \pi_{t-1}^*) + 0.10 \ y_{t-1} \right] + 0.26 \ \Delta \pi_t + 0.51 \ \Delta y_t + \eta_t,$$

where the estimated standard error of each coefficient is enclosed in parentheses. This reaction function exhibits a high degree of inertia, a strong long-run response to inflation, modest sensitivity to the level of the output gap, and a sizeable response to changes in the output gap.
Figure 2: Estimated posterior distributions (red solid lines) and prior distributions (blue dashed) for structural parameters.
As for the monetary policy shocks, we find that the inflation target $\pi^*_t$ has significant variation and exhibits very high persistence approaching that of a random walk, while the transitory disturbance $\eta^*_t$ has negligible variance. It should be noted that our modelling framework does not provide any rationale or potential benefits from a time-varying inflation target or from idiosyncratic disturbances to the policy rule. Thus, given our focus on policies that maximize social welfare, henceforth we eliminate these two shocks by setting their variances to zero.

4 Optimal Monetary Policy

In this section, we characterize the monetary policy implications of the baseline model at the posterior mean values of the estimated parameters, abstracting from uncertainty about the true structure of the economy. We start by considering the optimal policy under commitment that maximizes conditional expected welfare, and then compare the performance of simple rules in which the short-term interest rate is adjusted in response to one or more observable variables.

4.1 The Optimal Policy Problem

The optimal policy under commitment can be computed by formulating an infinite-horizon Lagrangian problem, in which the central bank maximizes conditional expected social welfare subject to the full set of non-linear constraints implied by the private sector’s behavioral equations and the market-clearing conditions of the model economy.\textsuperscript{33} The first-order conditions of this problem are obtained by differentiating the Lagrangian with respect to each of the endogenous variables (including the policy instrument) and setting these derivatives to zero. Of course, performing these derivations by hand would be extremely tedious; thus, we utilize the symbolic Matlab procedures developed by Levin and Lopez-Salido (2004).\textsuperscript{34}

We then proceed to analyze the behavior of the economy under optimal policy by com-

\textsuperscript{33}See Kydland and Prescott (1980), King and Wolman (1999), and Khan, King, and Wolman (2003).

\textsuperscript{34}These procedures are available on the Dynare website or on request from the authors.
bining the central bank’s first-order conditions together with the private sector’s behavioral equations and the market-clearing conditions. Thus, the size of the model is much larger under the optimal policy, because these first-order conditions take the place of a single interest rate reaction function, while the set of Lagrange multipliers is added to the list of model variables. Nevertheless, it should be emphasized that no new parameters have been added to the model, because the central bank’s first-order conditions involve the same structural parameters as in the behavioral equations and market-clearing conditions.

Because this set of non-linear equations involves rational expectations, numerical methods are required to characterize the equilibrium properties of the stochastic economy.\textsuperscript{35} Furthermore, while the first-order dynamics can be investigated by log-linearizing the model, higher-order methods are needed to evaluate conditional expected welfare.\textsuperscript{36} Therefore, we employ the \textit{DYNARE} software package of Juillard (2001) to compute the second-order approximation of the model economy.\textsuperscript{37}

Finally, as in Levin and Lopez-Salido (2004), our analysis is focused on evaluating the welfare cost of business cycles; that is, for each monetary policy regime, we measure how conditional expected welfare changes in response to the stochastic variation of the model economy.\textsuperscript{38} Throughout the paper, welfare costs are expressed in terms of the equivalent percent decline in steady-state consumption.

\textbf{4.2 Characteristics of Optimal Policy}

The deterministic steady state of the baseline economy is characterized by a zero inflation rate. In particular, as noted above, we assume that fiscal subsidies offset the steady-state monopolistic distortions to production and employment, while money is essentially absent from the baseline specification. Thus, in the absence of stochastic shocks, the central bank’s

\textsuperscript{35}Judd (1998) provides a general introduction and comparison of methods for solving non-linear rational expectations models.

\textsuperscript{36}See Kim and Kim (2003), Kim, Kim, Schaumburg, and Sims (2003), and Woodford (2003).

\textsuperscript{37}Because perturbation methods provide a local approximation around the steady state, our analysis does not consider the implications of the zero lower bound on nominal interest rates.

\textsuperscript{38}For this purpose, it is essential to utilize conditional mean-preserving spreads for the exogenous disturbances; see Levin and Lopez-Salido (2004) for further discussion.
sole task is to choose the constant inflation rate that minimizes the degree of cross-sectional
dispersion in prices and wages; indeed, by maintaining a zero inflation rate, monetary policy
succeeds in implementing the Pareto-optimal equilibrium in steady state.

The first-order implications of the optimal policy are shown in Figure 3, which depicts
the response of selected macro variables to an exogenous rise in the productivity factor. The
optimal policy (solid line) yields a path of short-term real interest rates that closely
resembles that of the “real business cycle” (RBC) economy with flexible wages and prices
(dot-dashed line); in contrast, real interest rates are nearly constant under the empirical
reaction function (dashed line). In the RBC economy, real wages initially rise about 3/4
percent; with a constant price level, this adjustment occurs solely through a surge in nominal
wage inflation. In contrast, the optimal policy for the baseline economy is mainly oriented
towards minimizing cross-sectional dispersion in wage rates, and hence permits a noticeable
decline in prices while nominal wage inflation remains close to zero.

Under the optimal policy (as in the RBC economy), the positive shock to productivity
induces a substantial decline in aggregate labor hours that is gradually reversed over the
subsequent year. Under the empirical reaction function, labor hours only decline for a single
quarter and then rise above baseline. These findings relate to the debate regarding the
empirical evidence of the response of hours to productivity shocks and the sensitivity of
these results to monetary policy.

We now compare the welfare implications of these policies for the baseline economy
with stochastic variation in all of the exogenous disturbances except the monetary policy
shocks. For each policy, Table 2 reports the welfare cost of business cycles in terms of the
equivalent percentage point change in steady-state consumption; this table also indicates
welfare outcomes for two simple rules that are discussed further below.

Under the empirical reaction function, the welfare cost of business cycles in the baseline
model is equivalent to a permanent 2.6 percent reduction in household consumption. The

39Impulse responses for other structural shocks are reported in the Appendix.
Figure 3: Impulse responses for one standard deviation positive shock to productivity; optimal policy (solid lines), empirical reaction function (dashed), RBC economy (dash-dotted lines).
optimal policy is associated with a markedly lower cost of business cycles, equivalent to about 2 percent of steady-state consumption. It should be noted that these welfare costs are an order of magnitude larger than in the results emphasized by Lucas (2003), mainly because staggered contracts induce substantial cross-sectional dispersion in relative prices and wages.\textsuperscript{40}

To gauge these welfare results more concretely, we note that U.S. personal consumption expenditures were about $28,000 per person in 2004; thus, switching from the empirical reaction function to the optimal policy would permanently raise welfare by about $160 per person, while eliminating all stochastic variation in the economy would generate a permanent welfare gain exceeding $700 per person. As we will see below, however, the magnitude of the welfare costs can be quite sensitive to the parameter values of the model as well as to the specification of the innovations and the determination of wages and prices.

### 4.3 Simple Policy Rules

We now consider the performance of simple policy rules with coefficients chosen to maximize welfare in the baseline model.\textsuperscript{41} In particular, we examine rules with the following form:

\[
    r_t = r_t r_{t-1} + r_t \pi_t + r_t \omega_t,
\]

where the nominal interest rate \( r_t \) responds to the price inflation rate \( \pi_t \) and the nominal wage inflation rate \( \omega_t \) as well as to the lagged nominal interest rate. Rules of this type are operational in the sense of McCallum (1999), in the sense that the policy instrument is

\textsuperscript{40}For related analysis and results, see Cho, Cooley, and Phaneuf (1997), Canzoneri, Cumby, and Diba (2004), and Paustian (2004).

\textsuperscript{41}For analysis and discussion of the rationale for simple rules, see Taylor (1993a) and Williams (2003).
determined only by observable variables, as opposed to model-specific constructed data such as the natural rates of interest and output, or forecasts of variables (that require knowledge of the economy).\footnote{McCallum (1999) also highlights the role of information lags; thus, while our specification utilizes contemporaneous data, it will be useful to consider this issue further in subsequent research.} Furthermore, this form of rule is equivalent to targeting a deterministic path for the level of wages or prices; such policies have been shown to perform very well in the presence of the zero lower bound on nominal interest rates.\footnote{See Reifschneider and Williams (2000), Eggertsson and Woodford (2003), and others.}

Given the role of wage dispersion in determining the welfare cost of business cycles, it is useful to consider policy rules that respond directly to nominal wage inflation, as suggested by Erceg, Henderson, and Levin (2000).\footnote{See also Erceg and Levin (2005) and Mankiw and Reiss (2002).} For this reason, we consider a hybrid rule that responds differentially to both price and wage inflation, as well as rules that respond to price inflation alone. Optimizing the coefficients of the hybrid rule to maximize welfare in the baseline model, we find that $r_\omega = 3.2$ while $r_\pi = 0$. Thus, given that the optimized rule does not actually respond to price inflation, we simply refer to this rule as the benchmark wage inflation rule. We then compare its performance to an alternative rule—henceforth referred to as the benchmark price inflation rule—for which welfare optimization yields $r_\pi = 2.1$ subject to the constraint that $r_\omega = 0$.

As indicated in Table 2, the benchmark wage inflation rule yields a welfare outcome nearly identical to the optimal policy; indeed, following this simple wage inflation rule rather than the optimal policy would incur a welfare cost equivalent to less than $35 per person per year. In contrast, the benchmark price inflation rule yields a welfare loss that is roughly the same as under the empirical reaction function.

The impulse response to the technology shock under the benchmark wage inflation rule mimics closely those of the optimal policy, as seen in Figure 4. One difference is that the benchmark wage inflation rule initially tightens monetary policy, causing a slightly excessive fall in labor hours and consumption at the onset of the shock. After a few quarters, however, the benchmark wage inflation rule gets back on track, and the paths of labor hours,
Figure 4: Impulse responses for one standard deviation positive shock to productivity: optimal policy (solid lines), optimized wage inflation rule (dashed lines), and the optimized price inflation rule (dash-dot lines).
consumption, and price and wage inflation are virtually identical to those obtained under the optimal policy. In contrast, the benchmark price inflation rule is overly stimulative at the onset of the shock, keeping price inflation near baseline but generating excessive nominal wage inflation.

5 Parameter Uncertainty

In this section, we explore the sensitivity of household welfare to variations in the parameters under the wage inflation policy rule optimized to the baseline parameters discussed in Section 3. We evaluate the performance of this rule in comparison with that of the optimal policy determined using the true values of the model parameters.

5.1 Estimated Parameters

We start by considering the effect of uncertainty as measured by our estimated posterior distribution. We compute the welfare losses associated with joint parameter uncertainty of the ten structural parameters together. For this purpose, we randomly select 5000 draws of the parameter vector from the posterior distribution described above. For each draw, we compute welfare under the optimal policy for the true set of parameters and under the benchmark wage inflation policy. Note that this method incorporates the covariance between the model parameters, allowing for the possibility that particular combinations of parameter realizations may have sizeable effects on outcomes. Figure 5 reports the results from this exercise; the upper panel shows the resulting distributions of welfare losses under the two policies and the lower panel shows the distribution of the relative welfare loss equal to the difference in welfare between the optimal policy and the benchmark wage inflation rule.

Uncertainty about the structural parameters implies a great deal of uncertainty regarding the welfare loss associated with fluctuations, but far less uncertainty regarding the performance of the benchmark wage inflation rule relative to the optimal policy. As seen in the

\footnote{We do not, however, vary the parameters associated with the shock processes or the calibrated parameters.}
Figure 5: The distribution of welfare losses for the estimated posterior distribution. Top panel: Welfare losses relative to the steady state for the optimal policy tuned to each parameter draw (red line) and the benchmark wage inflation rule (dashed blue line) Bottom panel: Difference in welfare loss between the optimal and benchmark wage inflation rule.
upper panel of the figure, the distribution of welfare losses under either policy is wide with a relatively long left tail. Under the optimal policy, the median welfare loss is 2.1 percent, just 0.1 percentage point larger than for the posterior mean estimates, but the 90 percent confidence interval for the welfare loss ranges from 4.3 percent to 0.9 percent. The results under the benchmark wage inflation rule are comparable. Thus, parameter uncertainty can easily make the welfare costs of fluctuations more than double what we estimate, or for that matter, be half as large. However, as the lower panel of the figure shows, the performance of the benchmark wage inflation rule relative to the optimal policy is remarkably robust to parameter uncertainty. Indeed, the mean relative welfare loss, evaluated over the posterior distribution, is 0.14 percent, compared to 0.12 percent assuming no uncertainty, and the 90 percent probability interval for the relative welfare loss is relatively narrow, ranging from 0.06 to 0.35 percent.

Because the benchmark rule performs so well across the posterior distribution, it is not surprising that taking account of parameter uncertainty as measured by the posterior distribution has virtually no effect on the parameters or expected performance of the optimized wage inflation rule. We computed the coefficient of a wage inflation rule that maximizes expected welfare integrating over the posterior distribution as above. The optimal coefficient equals 2.9, slightly lower than the value of 3.2 in the case of no uncertainty. But, this rule yields an increase in expected welfare relative to the benchmark wage inflation rule of only 0.0004 percent. Thus, the existence of parameter uncertainty, as measured by the posterior distribution, is nearly irrelevant for designing policy in this model. Of course, a significant reduction in this uncertainty could have implications for the design of policy and welfare, as we examine next.

The degree of parameter uncertainty represented by the posterior distribution likely understates the true degree of uncertainty that policymakers face. As discussed in Onatski and N. Williams (2003) and Lubik and Schorfheide (2005), the mean and spread of the posterior distributions are highly sensitive to the assumed prior distributions. Point estimates and
their standard errors are sensitive to estimation methodology, sample, and the values of calibrated parameters.\footnote{In addition, the welfare costs of fluctuations are very sensitive to the assumed degree of substitutibility across types of labor and of goods, parameters that we take as fixed in this analysis.} This sensitivity is illustrated by the wide range of point estimates for various model parameters found in what are nearly identical models studied by CEE, SW, and in this paper.

Given this concern that the degree of parameter uncertainty may exceed that implied by the posterior distribution, we now examine the robustness of the benchmark wage inflation rule to a much wider set of parameter values. A second goal of this analysis is to uncover which parameters are important for the design of monetary policy; that is, for which parameters are there large costs with having an estimate far from the true value. To facilitate our analysis, we vary specific parameters one at a time, holding all other parameters at their respective mean estimates. We focus our analysis on the difference in welfare between that found under the benchmark wage inflation rule and the optimal policy for the specified parameter. Again, we measure the potential loss in switching from the optimal policy (assuming the true parameter value were known) to the benchmark wage inflation rule (optimized for the baseline parameters).

We start with the parameters describing price and wage determination. Figure 6 plots the differences in the consumption-equivalent welfare losses between the optimal policy and the benchmark wage inflation rule as the four parameters related to price and wage setting are varied. The results for the Calvo parameters are shown in the upper panels; the results for the indexation parameters are shown in the lower panels. The vertical lines indicate the 5\% and 95\% posterior bounds for the parameters calculated from the Markov Chain Monte Carlo simulations. If the resulting plotted line is horizontal, estimation error for that parameter has no welfare costs, while a steeply sloped line indicates that parameter estimation error carries high costs and that better estimates potentially would have a large social benefit.

Although uncertainty regarding the wage and price parameters based on the estimated
Figure 6: Parameter uncertainty: price and wage setting. The difference between welfare under the benchmark wage inflation rule and the optimal policy is plotted as the dark red line. The two vertical lines indicate the 5 and 95 percent bounds from the posterior distributions.
probability intervals has very modest implications for the performance of the benchmark wage inflation rule, looked at from a broader, or an explicitly min-max, perspective, reducing uncertainty about price and wage-setting parameters potentially could yield moderate benefits in terms of monetary policy design and welfare. The relative performance of the benchmark wage inflation rule is sensitive to very high values of the Calvo wage parameter. For the other Calvo price and indexation parameters, the performance of the benchmark wage inflation policy drops off if prices are reoptimized very frequently or if a high share of contracts are indexed, neither of which are likely according to the posterior distribution. For example, consider the case that the true Calvo price parameter, $\xi_p$, is as low as some of the micro evidence suggests. According to the posterior distribution, such a low value is extremely unlikely. But, if true, knowledge of this parameter could be used to design a monetary policy that yields a moderate improvement in welfare. The same applies for the Calvo wage and price indexation parameters. Although the degree of wage indexation is imprecisely estimated, the relative welfare loss is nearly invariant to the value of this parameter.

Figure 7 plots the results for the parameters related to preferences and technology. Given the estimated precision of these parameter estimates, parameter uncertainty has trivial implications for welfare and therefore for policy. For example, although $\chi$, the parameter measuring the disutility of labor, is imprecisely estimated, it has a modest effect on relative welfare.

It should be noted that the parameter $\phi$, which measures the degree of increasing returns, does have a significant effect on relative welfare under the benchmark wage rule. With a loose prior, we would estimate a value for this parameter near 2. Assuming that the results of the literature indicating at most modest increasing returns are true, the resulting reduction in uncertainty has a large effect on welfare in this model assuming policy is designed to be optimal at the baseline estimates. Moreover our estimate of the habit persistence parameter is on the low side of recent estimates, which tend to find values in the 0.5-0.7 range. Once
Figure 7: Parameter uncertainty: other structural parameters. The difference between welfare under the benchmark wage inflation rule and the optimal policy is plotted as the dark red line. The two vertical lines indicate the 5 and 95 percent bounds from the posterior distributions.
again, we find such values to be unlikely but we find a significant drop in the performance of the benchmark wage inflation rule when the habit parameter increases past 0.5. Finally, knowledge of the true magnitude of investment adjustment costs would be valuable for policy design.

5.2 Steady-state Markups

As noted above, we cannot estimate the steady-state price and wage markups using the first-order dynamics of the model, but instead calibrate both to be 20 percent. Given the uncertainty regarding the values of these parameters, we briefly explore the implications of alternative calibrations of the steady-state markups for monetary policy.

The magnitude of welfare losses depends on the steady-state price markup, but the performance of the benchmark wage inflation rule relative to the optimal policy is insensitive to this parameter. We evaluate the welfare losses under four representative monetary policies analyzed above as $\lambda^p$ is varied from 0.1 to 0.5, holding all other parameters fixed. Recall that the steady-state price markup does not affect the first-order properties of the system.\(^{47}\)

The results are shown in the upper part of Table 3. Welfare losses are larger, the smaller is the steady-state price markup, reflecting the effect of greater dispersion when goods are more highly substitutable. The relative performance of the various policies is insensitive to the value of the steady-state price markup.

The welfare losses are highly sensitive to the value of the steady-state wage markup, and for very high values of this parameter, the performance of the benchmark price inflation policy rule approaches that of the benchmark wage inflation rule. In considering the effects of variations in $\lambda^w$, we vary the value of Calvo wage parameter, $\xi_w$, so that the first-order properties of the model are constant.\(^{48}\) We hold all other parameter values fixed at baseline values. Note that even with a high steady-state wage markup, the benchmark wage inflation

---

\(^{47}\)Note that we do not impose a relationship between the fixed cost parameter and the markup implied by a zero-profit condition.

\(^{48}\)Thus, we isolate the effects of changing the substitutability of different types of labor on welfare from those on the sensitivity of wages to movements in the marginal rate of substitution.

policy rule performs well, although the difference between it and the rules that respond to price inflation is much smaller than in the baseline model.

6 Innovation Uncertainty

We now consider alternative assumptions regarding the set of shocks in the model. In computing welfare, we have had to take a stand on each shock as to whether it reflects shifts in fundamentals, the effects of distortions, or measurement error. In particular, we have assumed that the wage and price shocks and the shocks to the external finance premium are distortionary, while the remaining shocks reflect shifts in fundamentals. We now revisit these assumptions and evaluate the performance of the various monetary policies under alternative assumptions regarding the nature of innovations.

The baseline model is admittedly profligate in specifying shocks. In particular, the external finance premium has a large estimated variance and may be important for welfare according to the model, but arguably lacks microfoundations. Importantly, we have assumed that this shock does not affect fundamentals, but instead represents inefficient fluctuations in an external finance premium or a type of “animal spirits” that monetary should counteract. In contrast, we have assumed that investment adjustment costs shocks reflect fundamentals and their effects should be accommodated. We therefore consider an alternative model spec-

Elimination in which these shocks do not exist, that is, Tobin’s Q strictly follows fundamentals. We assume that these shocks represent measurement error evident in estimating the model, but have no effects on the actual allocation of resources. We do no re-estimate the model, but rather simply set the variance of the external finance premium shocks to zero.\(^{49}\) The second line of Table 4 reports the results from this experiment. Interestingly, eliminating the external finance premium shocks has little effect on welfare or the relative performance of the various policy rules.

We further examine how the policy rules perform under alternative assumptions regarding the nature of shocks to price and wage markups. In the baseline model, these shocks are viewed as being distortionary movements in markups. We now consider the possibility that these disturbances simply reflect measurement error. Again, we do not re-estimate the model, but instead simply zero out these residuals. We consider each shock in isolation and the combined effect. The results are shown in the upper part of Table 4.

Eliminating either markup shock reduces the welfare costs of fluctuations, but does not

\(^{49}\)In a previous version of this paper, we estimated an alternative model that included no external finance premium shocks. Estimates of most model parameters were nearly identical to the baseline estimates. Exceptions included the estimate of \(\zeta\), which fell, implying significantly higher costs of adjusting investment, and the investment adjustment cost shock became more variable and less persistent. The effects on welfare of this specification were modest.
alter the relative performance of the various policy rules. The welfare gap between the optimal policy and the benchmark wage inflation rule is cut in half, relative to that in the baseline specification, to only 0.06 percentage points in terms of foregone consumption. The price shocks have relatively little effect on welfare; the wage shocks, however, are an important source of welfare loss under both the optimal and the benchmark policies, but have little effect on the relative performance of the benchmark wage inflation policy rule.

Finally, we consider the nature of disturbances to preferences. In the baseline model, we have assumed that shocks to time preference and the disutility of labor reflect fundamental movements in the economy that monetary policy should accommodate. We consider two alternative assumptions. First, we assume that the shocks merely reflect measurement error and evaluate the four policies under the assumption that the preference shock does not exist. As before, we consider each shock in isolation. Interestingly, eliminating either preference shock increases welfare under the various policies by about 0.25 percentage point; that is, stochastic shocks to preferences are welfare-enhancing in our baseline model. The performance of the benchmark wage inflation rule relative to the optimal policy is virtually unchanged. Second, we consider the assumption that the preference shocks reflect non-fundamentals, such as changes in tax rates. The results are shown in the lower section of Table 4. In this case, the welfare losses are significantly higher than in the baseline model, but, again, the performance of the benchmark wage inflation rule relative to the optimal policy does not deteriorate.

Regardless of the assumption regarding the nature of these shocks, the benchmark wage inflation rule is nearly optimal and outperforms by a significant margin the estimated and benchmark price inflation rules. In summary, although innovation uncertainty exacerbates the already significant uncertainty regarding the magnitude of the welfare costs of fluctuations, the benchmark wage inflation rule is remarkably robust to changes in assumptions regarding the nature of shocks hitting the economy.

50Because a shock to preferences affects only welfare and not the production possibilities of the economy, with flexible wages and prices, welfare is non-decreasing to a mean-preserving spread to preferences.
7 Specification Uncertainty

We now proceed to consider the broader problem of specification uncertainty in the sense of Leamer (1978). In specifying the baseline model, we made numerous choices that affect the parameter estimates, the structure of the model, and the determinants of welfare. In this section, we analyze the sensitivity of optimal policies to alternate assumptions regarding the model specification and evaluate the marginal benefit of reducing uncertainty of each of the key specification issues in terms of social welfare. As in the preceding section, this analysis provides information on the value, from the perspective of monetary policy, in improving our knowledge of specification issues and suggests where the highest payoffs are for further research in this area. While the list of specifications we consider is far from exhaustive, it provides some examples of the type of specification uncertainty that may be important for policy analysis.

7.1 Monetary Frictions and Working Capital

Our baseline model can be viewed as a “cashless economy” that completely abstracts from monetary frictions. We now investigate the policy implications of incorporating household demand for money as well as working-capital considerations for firms. First, we permit the scale parameter $\mu_0$ to have a non-trivial value, so that real money balances have direct effects on household utility. Second, following Christiano, Eichenbaum, and Evans (2005), we assume that firms must borrow from financial intermediaries to cover their wage bill and then repay the loan at the end of the period. Thus, assuming that these funds can be obtained at the gross risk-free nominal interest rate, firms’ total labor costs are now given by $R_t W_t L_t$.

Since we specify that policy is conducted via an interest rate rule, we do not need to concern ourselves with market clearing in the loan market. This would only serve to pin down the value of broad money. Instead, we simply append the portfolio allocation decision

\[51\text{For some early analysis of specification uncertainty in structural models, see Becker, Dwolatsky, Karakitsos, and Rustem (1986) and Frankel and Rockett (1988).}\]
to determine the household’s cash balances (which now affect welfare), and we incorporate the effects of working capital on firms’ labor demand and marginal costs. We then re-estimate the model, using data on cash balances in addition to the seven variables noted above.\textsuperscript{52} The mode estimate of the preference parameter $\kappa$ is 11.4, while the mode estimates of all other model parameters are nearly the same as in the baseline specification.\textsuperscript{53}

The modified model has two key implications for policy. First, owing to the effects of nominal interest rates on costs and money balances, the optimal inflation rate is no longer zero, but instead slightly below zero. Second, there is a cost to highly variable nominal interest rates that is absent in the baseline model and a resultant benefit to smoothing interest rates. As a result, the optimal wage inflation policy rule responds less aggressively to wage inflation, with a coefficient of 1.5, compared to 3.2 in the baseline model.\textsuperscript{54} The benchmark wage inflation rule yields a welfare loss 0.07 percentage points in terms of permanent consumption greater than the rule optimized for this alternative model with monetary frictions and working capital.

### 7.2 Alternative Models of Wage Setting

A key result in our analysis is the importance of stabilizing wages owing to the distortions associated with wage dispersion under Calvo-style contracts. Given the central role of this channel we consider alternative specifications of wage setting that have significant effects on the welfare implications of sticky wages and for optimal policy. In particular, we consider two alternative specifications in which the effects of wage dispersion on welfare are muted relative to the Calvo-style model.\textsuperscript{55}

We first consider a modest modification to the indexation of wages in the model and assume that non-optimized wages are indexed to last period’s wage inflation rate, as opposed

\textsuperscript{52}The money data is only available from 1959 onward, so we shorten the sample by four years. Linearized expressions are again given in the appendix.

\textsuperscript{53}Complete estimation results are reported in Appendix C.

\textsuperscript{54}It is still the case that the optimal coefficient on price inflation is zero.

\textsuperscript{55}Although not considered here, another model of wage and price setting that does not yield dispersion effects on aggregate welfare is the quadratic adjustment costs model of Rotemberg (1982).

to rate of price inflation. This modification to the model reduces the effects of fluctuations in wage inflation on wage dispersion and thereby welfare.\(^{56}\) Table 4 reports the results from this specification for four specifications of monetary policy. Not surprisingly, the consumption-equivalent loss in conditional welfare under the optimal policy is somewhat smaller than in the baseline model.

The relative performance of the benchmark wage inflation rule, however, is considerably worse under this form of wage indexation, and is dominated by the rule that responds only to price inflation. Under the benchmark wage inflation policy rule, the consumption-equivalent loss in conditional welfare is 0.6 percentage points larger than under the optimal policy and 0.3 percentage points higher than under the benchmark price inflation rule. In fact, with this specification of wage indexation, the benchmark wage inflation policy rule does slightly worse than the estimated policy rule. Evidently, the result that a simple policy rule designed to maximize welfare should respond exclusively to wage inflation is not robust to changes in the model of wage determination, even to this seemingly innocuous change in the model specification.

We now consider a more substantive change in the specification of wage and price determination, and assume that contracts have fixed duration as in Taylor (1980); see also Chari, Kehoe, and McGrattan (2000).\(^{57}\) Compared with the baseline specification of Calvo-style

---

\(^{56}\) We estimated a version of the baseline model where wage indexation depends on a combination of past price and wage inflation. We found that the weight is primarily on past price inflation, providing support for the baseline model specification. Nonetheless, one may not be convinced by this finding and remained concerned about uncertainty regarding the form of wage indexation.

\(^{57}\) As explained below, we have not formally estimated this alternative specification. The empirical performance of the model may be sensitive to which type of nominal rigidity is assumed; see Chari, Kehoe, and McGrattan (2000), Kiley (2002), and Guerrieri (2001).
contracts with random duration, this alternative specification limits the degree of price and wage dispersion—and the associated welfare costs—resulting from the presence of some prices and wages that have not been reoptimized for many periods.

We suppose that nominal wages and prices are determined by staggered contracts that are reset every $M$ periods. Thus at $t$ the distribution of wages is given by $\{W_{t,j}\}$ where $j = 1, \ldots, M$ denotes the number of periods since the last re-set. In particular, we assume that all price and wage contracts last for four quarters, implying mean contract durations somewhat shorter than implied by our posterior mean estimates of the Calvo update parameters, $\xi_p$ and $\xi_w$. We do not change any other parameter estimates and revert to the baseline assumption that wages are indexed to past price inflation. The results are reported in Table 5. As expected, replacing Calvo-style wage and price setting with Taylor-style contracts significantly reduces wage and price dispersion and hence the welfare costs associated with fluctuations.

With Taylor-style staggered wages and prices, the relative performance of the benchmark wage inflation rule falls dramatically, while the estimated policy rule is nearly optimal. The benchmark price inflation rule outperforms the benchmark wage inflation rule, but falls behind the estimated rule. With Taylor price and wage contracts, the welfare costs associated with price and wage dispersion are relatively modest and, therefore, the optimal policy focusses on coming close to the real allocation in the flexible wage and price economy. The estimated rule accomplishes this balance very well, while the benchmark price inflation rule is somewhat less effective owing to a lack of response to the output gap. The performance of the benchmark wage inflation rule suffers more significantly because it implicitly puts far too much emphasis on stabilizing nominal wage inflation relative to achieving the flexible wage and price real allocation.\footnote{We also examined a version of the model with Taylor wage contracts and Calvo prices. The results were very similar to those found when both wages and prices are set by Taylor contracts.}

Finally, it should be noted that the welfare cost of business cycles and the performance of alternative monetary policies are sensitive not only to the structure of nominal contracts but
to the specification of household preferences. For example, as in CEE and SW, our analysis has followed Erceg, Henderson, and Levin (2000) in assuming that each individual household provides a distinct labor service, whereas Schmitt-Grohe and Uribe (this volume) assume that each household has a continuum of members providing all types of labor services and that the household’s utility only depends on its total hours of work. While such assumptions might seem to be merely technical details, in fact these differences have fairly dramatic consequences for the first-order dynamics of wage inflation, the second-order effects of cross-sectional wage dispersion, and the design of welfare-maximizing policy rules.\footnote{The specification of Erceg, Henderson, and Levin (2000) implies a much flatter nominal wage Phillips curve; that is, nominal wage inflation is much less sensitive to the marginal rate of substitution between consumption and leisure. Furthermore, cross-sectional wage dispersion induces differences in labor across households that have substantial effects on social welfare.}

8 Conclusion

Over the past decade there has been remarkable progress in developing empirical micro-founded macroeconomic models for monetary policy analysis. In this paper we have drawn on and extended this literature to consider the design of policy under uncertainty. By confronting a fully-specified dynamic stochastic general equilibrium with the data, we can directly gauge the uncertainty associated with the model parameters as well as the implications of alternative assumptions regarding the model specification.

Our analysis indicates that the welfare cost of business cycles is quite large—an order of magnitude larger than the findings emphasized by Lucas (2003)—and arises mainly due to inefficiencies associated with cross-sectional dispersion in wages and employment. As a direct consequence, we find that the welfare outcome associated with optimal policy under commitment is closely matched by a very simple rule that responds solely to nominal wage inflation. Furthermore, the performance of this benchmark wage inflation rule is remarkably robust to uncertainty about the structural parameters and the particular shocks hitting the economy. The performance of this rule is very sensitive to the specification of wage and price determination, suggesting that a hybrid rule involving both wage and price inflation might
be more robust across a broader class of models.

These findings underscore the central importance of labor markets for analyzing the welfare costs of macroeconomic fluctuations and the design of monetary policy. Of course, the crucial role of wage setting and employment dynamics has long been recognized, and recent research has refocused interest on these issues; see Hall (2005). Thus, further progress in formulating micro-founded specifications of labor market behavior and comparing the empirical performance of these specifications is likely to have substantial payoffs for the design of monetary policy.

Finally, while our analysis has emphasized the implications of policymaker uncertainty regarding the true structure of the economy, we have abstracted completely from the role of learning by policymakers or private agents. Nevertheless, we recognize that the learning mechanism is crucial for understanding the evolution of the economy in response to changes in the monetary policy regime—such as the Volcker disinflation—and to other aggregate disturbances.60 Thus, incorporating learning in micro-founded macroeconometric models and reconsidering the policy implications represents a natural direction for future research.61

---

60Erceg and Levin (2003) analyze a DGE model roughly similar to the one in this paper and show that private agents’ gradual learning about the Fed’s inflation objective is crucial for interpreting the effects of the Volcker disinflation, while Edge, Laubach, and J. Williams (2003) and Erceg, Guerrieri, and Gust (2005) highlight the role of learning in fitting the stylized facts of the U.S. productivity growth boom of the late 1990s.

61See Beck and Wieland (2002) for analysis of optimal learning and control in a small stylized economy with ongoing structural change.

Appendix

A The Nonlinear Model

A.1 The Baseline Model

The text describes the household side, and we now fill in some detail on the firm side. Define the capacity utilization cost function from (5) by:

$$\Psi(U_t) = \mu \frac{U_t^{1+\psi^{-1}}}{1+\psi^{-1}},$$

where $\psi$ is the inverse of the elasticity of utilization cost with respect to utilization, and $\mu$ is chosen so that steady state utilization costs are zero. Also define the investment adjustment cost function from (4) by:

$$S(Z_t I_t(i)/I_{t-1}(i)) = \zeta^{-1} \frac{1}{2} \left( \frac{Z_t I_t(i)}{I_{t-1}(i)} - 1 \right)^2.$$

Note that adjustment costs are assumed to be zero at the steady state, $S(1) = 0$, and are only of second-order at the steady state.

Index households by $h$ and firms by $i$. Then denote by $N_t(i)$ plant $i$’s labor input given by

$$N_t(i) = \left[ \int_0^1 L_t(i, h)^{\frac{1}{1+\lambda_w}} \, dh \right]^{1+\lambda_w},$$

where $L_t(i, j)$ is the input of labor of type $j$ at plant $i$. The plant’s output is given by (3).

Aggregate final good output, $Y_t$ is created by (costlessly) combining a continuum of intermediate goods, $Y_t(i)$, indexed by $i$:

$$Y_t = \left[ \int_0^1 Y_t(i)^{\frac{1}{1+\lambda_p}} \, di \right]^{1+\lambda_p}. \quad (7)$$

Final goods output is equal to consumption, aggregate investment, $I_t$, government spending, $G_t$, and capital utilization costs:

$$Y_t = C_t + G_t + I_t + \Psi(U_t)K_{t-1}. \quad (8)$$

A.2 Equilibrium Allocation and Prices

In the following, we omit household and plant indices where no confusion will result. The household’s budget constraint is standard and households trade in a complete market to allocate their consumption over time. Let $MUC_t$ denote the marginal utility associated with an incremental increase in consumption in period $t$, accounting for its effect on period utility
in the period $t + 1$:

$$MUC_t = Z_t^b (C_t - \theta C_{t-1})^{-\sigma} - \beta \theta E_t Z_{t+1}^b (C_{t+1} - \theta C_t)^{-\sigma}$$

(9)

The consumption Euler equation summarizes the representative household’s optimal saving behavior:

$$MUC_t = E_t [MUC_{t+1} R_t P_t / P_{t+1}]$$

(10)

where $R_t$ is the gross nominal interest rate and $P_t$ is the price level.

Households set wages subject to their individual labor demand curves, which arise from the firms’ input demands. The evolution of the aggregate nominal wage index is:

$$W_t^{-1/\lambda^w} = \xi_w W_{t-1}^{-1/\lambda^w} \left( \frac{P_{t-1}}{P_{t-2}} \right)^{-\gamma_w/\lambda^w} + (1 - \xi_w) \bar{w}_t^{-1/\lambda^w}. \quad (11)$$

Here $\bar{w}_t$ is the optimal nominal wage chosen by those households who can optimize in the period, which satisfies:

$$\frac{\bar{w}_t}{P_t} E_t \sum_{i=0}^{\infty} \beta^{i+1} \xi_{t+i}^w L_{t+i}(h) e_{t+i}^b \left[ \frac{P_{t-i} P_{t-i+1}}{P_{t-i-1} P_{t-i}} \right]^{\gamma_w} \frac{MUC_{t+i}}{1 + \lambda^w_{t+i}} - Z_t^L (L_{t+i}(h))^{\chi} = 0. \quad (12)$$

As in usual Calvo pricing models, (12) incorporates forward-looking expectations of future nominal wages, but now includes lagged inflation via the partial indexation.

Households own the capital stock $K_t$, which they accumulate using the capital accumulation technology, and rent to firms at rental rate $R_k^t$. This leads to three key relationships. First, we let $Q_t$ be the real share value per unit of capital which is determined by an asset pricing Euler equation from (10):

$$Q_t = Z_t^q E_t \left[ \beta \frac{MUC_{t+1}}{MUC_t} \left( Q_{t+1}(1 - \delta) + U_{t+1} R_{t+1}^k - \Psi(U_{t+1}) \right) \right], \quad (13)$$

where $Z_t^q$ is the i.i.d. external finance premium shock. The optimal investment decision leads to an investment Euler equation:

$$1 - Q_t S' \left( \frac{Z_t^I I_t}{I_{t-1}} \right) \frac{Z_{t+1}^I I_t}{I_{t-1}} = E_t \left[ \frac{MUC_{t+1}}{MUC_t} Q_{t+1} S' \left( \frac{Z_{t+1}^I I_{t+1}}{I_t} \right) \frac{Z_{t+1}^I I_{t+1}}{I_t} \right] \quad (14)$$

This equation balances the costs and benefits of investment, with lagged investment and the shocks showing up through the effects of the costs of adjustment. Finally, the first order condition for utilization gives:

$$R_k^t = \Psi'(U_t). \quad (15)$$

On the production side, the firms’ cost minimization conditions are symmetric and given by:

$$\frac{W_t L_t}{R_k^t U_t K_{t-1}} = \frac{1 - \alpha}{\alpha}. \quad (16)$$

Thus firms equate the marginal rate of transformation between labor and effective capital
\( (U_t K_{t-1}) \) to the relative factor prices, and the capital-labor ratio is identical across firms. Marginal costs are then given by:

\[
MC_t = \frac{W_t^{1-\alpha} (R_k^t)^\alpha}{\lambda_t} \alpha^{-\alpha} (1 - \alpha)^{\alpha-1}. \tag{17}
\]

The evolution of the aggregate nominal price index is:

\[
P_t^{-1/\lambda_t^f} = \xi_p P_{t-1}^{-1/\lambda_t^f} \left( \frac{P_{t-1}}{P_{t-2}} \right)^{-\gamma_p/\lambda_t^f} + (1 - \xi_p) \bar{p}_t^{-1/\lambda_t^f} \tag{18}
\]

Here \( \bar{p}_t \) is the optimal price chosen by those firms who can optimize in the period, which satisfies:

\[
E_t \sum_{s=0}^\infty \beta_t^s \xi_{sp} \lambda_{t+s}^P Y_{t+s} (i) \mu C_{t+i} + \frac{\bar{p}_t}{P_t} \left( \frac{P_{t+s}}{P_{t-1}} \right)^{\gamma_p} - (1 + \lambda_{t+s}^P) \frac{MC_{t+s}}{P_{t+s}} = 0. \tag{19}
\]

Finally, we close the model by specifying an empirical monetary policy reaction function. We specify policy in terms of a generalized Taylor-type rule, where the policy authority sets nominal rates in response to inflation and the output gap. To do this, we define a model-consistent output gap as the difference between actual and potential output, where potential output is defined as what would prevail under flexible prices and wages and in the absence of the three “cost-push” shocks \( Z_{supportive}^p, Z_{supportive}^q, Z_{supportive}^r \) that cause variations in wage and price markups and the external finance premium. Thus the model is supplemented with flexible-price versions of the key equations (10)-(18) which determine the potential output \( Y^*_t \). Then the policy rule is assumed to take the following form:

\[
r_t = r_t r_{t-1} + \left( 1 - r_t \right) \left( \pi_t + \pi_t (\pi_t - \pi_{t-1}) + \gamma\log(Y_t/Y_{t-1}) \right) + \gamma\Delta\pi_t (\pi_t - \pi_{t-1}) + \gamma\Delta y_t \left( \log(Y_t/Y^*_t) - \log(Y_{t-1}/Y^*_t) \right) + \eta_t R_t. \tag{20}
\]

Here \( r_t = \log R_t \) is the short-term interest rate, \( \pi_t = \Delta \ln(P_t/P_{t-1}) \) is the inflation rate, \( \pi^*_t \) is an \( AR(1) \) shock to the inflation objective, and \( \eta_t^R \) is an i.i.d. policy shock.

### A.3 The Model with Monetary Frictions

In the model with monetary frictions from Section 7.1, the household also has a portfolio allocation decision. The first order condition is:

\[
Z_t^h e_t^m (M_t/P_t)^{-\alpha} = (R_t - 1) C_t. \tag{21}
\]

Thus the cost minimization condition (16) now becomes:

\[
\frac{R_t W_t L_t}{R_t^k U_t K_{t-1}} = \frac{1 - \alpha}{\alpha} \tag{22}
\]
In turn, the marginal cost changes from (17) to:

$$ MC_t = \frac{(R_t W_t)^{1-\alpha}(R_k^m)^{\alpha}}{A_t} \alpha^{-\alpha(1-\alpha)^{\alpha-1}}. $$ (23)

Market clearing in the loan market then implies:

$$ W_t L_t = A_t - M_t, $$

where \( A_t \) represents level of broad money after the infusion of money via the central bank.

### A.4 The Model with Staggered Contracts

In the model with staggered contracts from Section 7.2, we must make a few alterations to the model. We again allow for partial indexation so the evolution of an individual household’s wage is given by:

$$ W_{t,j} = \left( \frac{P_{t-1}}{P_{t-2}} \right)^{\gamma_p} W_{t-1,j-1} \text{ if } j \neq M $$

$$ = \tilde{w}_t \text{ if } j = M. $$

The aggregate wage index changes from (11) to:

$$ W_t^{-1/\lambda_t^w} = \frac{1}{M} \sum_{j=1}^{M} W_{t,j}^{-1/\lambda_t^w}. $$ (24)

Finally, the optimal wage choice satisfies:

$$ \frac{\tilde{w}_t}{P_t} E_t \sum_{i=0}^{M-1} \beta_{t+i} L_{t+i}(h) \left[ \left( \frac{P_t P_{t+i-1}}{P_{t-1} P_{t+i}} \right)^{\gamma_w} \frac{MUC_{t+i}}{1+\lambda_{t+i}^w} - \epsilon^l_t(L_{t+i}(h))^\lambda \right] = 0. $$ (25)

### B The Linearized Model

#### B.1 Baseline Model

For much of the paper we work with the log-linearized version of the model described above, which we present here. We use lower-case letters indicates the logarithmic deviations from steady state. In the case of shocks, \( \epsilon_t^x \) and \( \eta_t^x \) refer to the shocks normalized to the log-linear equations, with the \( \epsilon \) shocks being persistent and the \( \eta \) shocks i.i.d.

To save on notation, we define \( \bar{R}_k \) as the mean real rate of return on capital which is assumed to satisfy \( \beta = 1/(1 - \delta + \bar{R}_k) \), and \( \phi \) equals 1 plus the share of fixed costs in production. Furthermore, we denote \( c_y, g_y, \) and \( k_y \) as the steady state ratios of consumption, government spending, and capital to output, respectively.

The following ten equations in ten endogenous variables \( \{c_t, i_t, q_t, k_t, r_t^k, u_t, l_t, y_t, w_t, \pi_t\} \)
are the linearized counterparts to the equations described in the previous subsection:

\[
c_t = E_t \frac{1}{1 + \theta + \theta^2} \left\{ \theta c_{t-1} + (1 + \beta \theta^2 + \beta \theta)c_{t+1} - \beta \theta c_{t+2} \right\},
\]

\[
q_t = - (r_t - E_t \pi_{t+1}) + \frac{1}{1 - \delta + \bar{R}^k} \left\{ (1 - \delta) E_t q_{t+1} + \bar{R}^k E_t \pi_{t+1}^k \right\} + \eta_t^q,
\]

\[
i_t = \frac{1}{1 + \beta} E_t \left\{ i_{t-1} + \beta i_{t+1} + \zeta q_t + \beta (\epsilon_{t+1}^i - \epsilon_t^i) \right\},
\]

\[
k_t = (1 - \delta) k_{t-1} + \delta i_t,
\]

\[
u_t = \psi r_t,
\]

\[
l_t = - w_t + r_t^k + u_t + k_{t-1},
\]

\[
y_t = c_y c_t + g_y \epsilon_t^y + \delta k_y i_t + \bar{R}^k k_y u_t,
\]

\[
y_t = \phi (\epsilon_t^a + \alpha (u_t + k_{t-1}) - (1 - \alpha) l_t),
\]

\[
w_t = \frac{1}{1 + \beta} E_t \left\{ \beta w_{t+1} + w_{t-1} + \beta \pi_{t+1} - (1 + \beta \gamma_w) \pi_t + \gamma_w \pi_{t-1} \right\}
\]

\[
- \frac{\lambda_w (1 - \beta \xi_w) (1 - \xi_w)}{(\lambda_w + (1 + \lambda_w) \xi_w)} \left( w_t - \chi l_t - \epsilon_t^L + \frac{\beta \theta}{1 - \beta \theta} (\epsilon_t^b - \epsilon_{t+1}^b) - \eta_t^w \right),
\]

\[
- \frac{\sigma}{(1 - \theta) (1 - \beta \theta)} \left( 1 + \beta \theta^2 \right) c_t - \theta c_{t-1} - \beta \theta c_{t+1} \right\},
\]

\[
\pi_t = \frac{1}{1 + \beta \gamma_p} \left\{ \beta E_t \pi_{t+1} + \gamma_p \pi_{t-1} + \frac{(1 - \beta \xi_p) (1 - \xi_p)}{\xi_p} (\alpha \epsilon_t^k + (1 - \alpha) w_t - \epsilon_t^a + \eta_t^p) \right\}.
\]

As shown in Onatski and N. Williams (2004), equation (32) corrects a slight error in Smets and Wouters (2003a) due to the capital utilization costs which enters as the final term.

In addition, there are ten equations for the shock processes, six of which, \{\epsilon_t^a, \epsilon_t^y, \epsilon_t^b, \epsilon_t^i, \epsilon_t^L\}, follow AR(1) processes of the form:

\[
\epsilon_t^x = \rho_x \epsilon_{t-1}^x + \nu_t^x,
\]

where \nu_t^x is a mean zero innovation with variance \sigma_x^2. The remaining four shocks, \{\eta_p^t, \eta_i^t, \eta_q^t, \eta_w^t\}, are assumed to be i.i.d. with mean zero and variance \sigma_x^2. The innovations are assumed to have zero contemporaneous correlation.

The full model also includes counterparts to equations (26)-(33) that describe the log-linearized equations for the flexible-price allocation. In these equations, the shocks \eta_p, \eta_i, and \eta_w are set to zero, as is the inflation rate. The nominal interest rate is replaced by the flexible-price real interest rate, \(r_t^*\). This yields nine equations and nine additional variables, \{\epsilon_t^a, \epsilon_t^y, \epsilon_t^b, \epsilon_t^i, \epsilon_t^L, \eta_t^p, \eta_t^i, \eta_t^q, \eta_t^w\}, where the asterisk superscript denotes the flexible-price value of the variable.
We close the model by including the linearized counterpart to the policy rule:

\[ r_t = r_{i_t} + (1 - r_i)\left(\pi_t + r\pi(\pi_{t-1} - \pi_{t-1}^*) + r_y(y_{t-1} - y_{t-1}^*)\right) + r_{\Delta}\pi(\pi_t - \pi_{t-1}) + r_{\Delta y}(y_t - y_t^* - (y_{t-1} - y_{t-1}^*)) + \eta_t. \]  

(37)

\[ -\kappa m_t + \epsilon_t^m = \frac{\bar{R}}{R - 1} r_t + \frac{\sigma}{(1 - \theta)(1 - \beta)}((1 + \beta\theta^2)c_t - \theta c_{t-1} - \beta\theta E_t c_{t+1}) - \frac{\beta\theta}{1 - \beta}(\epsilon_t^b - E_t \epsilon_{t+1}^b) \]

(38)

where \( m_t \) is the log-deviation of real cash balances. Here \( \bar{R} \) is the steady state gross nominal rate which satisfies \( \bar{R} = 1 + \bar{R}^k - \delta \). Linearizing (22) we see that we replace (31) with:

\[ l_t = -w_t - r_t + r_k^t + z_t + k_{t-1} \]

(39)

Linearizing (23) we see that we replace (36) with:

\[ \pi_t = \frac{1}{1 + \beta\gamma_p}\left\{\beta E_t \pi_{t+1} + \gamma_p \pi_{t-1} + \frac{(1 - \beta\xi_p)(1 - \xi_p)}{\xi_p}(\alpha r_k^t + (1 - \alpha)(w_t + r_t) - \epsilon_t^a + \eta_t^p)\right\}. \]

\[ \]  

C Estimation Details and Results

C.1 Specification of the Priors

Table 6 reports the details of the specification of the prior for the model.\(^{62}\) For the parameters of the shock processes, where we had little guidance from the literature, so set relatively loose priors. For the standard deviations, we used gamma distributions with standard deviations equal to the means. We gauged the relative magnitudes of the shocks from Onatski and N. Williams (2004) and Smets and Wouters (2003a). For all but one persistence parameter, we used a wide beta distribution. The exception was the inflation objective shock. Since it and the interest rate shock enter additively in the policy rule (37) a tighter prior is necessary to distinguish between them. For the structural parameters, we chose the parameters of the distributions to cover with reasonably high probability the range of estimates we found in the literature.

C.2 Computation of the Posterior

As in Smets and Wouters (2003a), we first look for a parameter vector which maximizes the posterior mode, given our prior and the likelihood based on the data. We took great

---

\(^{62}\) For a brief survey of the literature on specification of priors, see Onatski and N. Williams (2004). This survey includes studies focusing on real models (such as King and Rebelo (1999) and Boldrin, Christiano, and Fisher (2001)) as well as papers focusing on monetary policy in smaller models (such as Rotemberg and Woodford (1997), Judd and Rudebusch (1998), Sack (1998)).

efforts to explore the parameter space sufficiently to locate a global maximum. In particular, we sampled 200 values from the prior distribution, and used these as starting values for Chris Sims’s optimization algorithms designed to avoid common problems with likelihood functions (available on his web page). We re-ran it in combination with a standard hill-climber algorithm until it settled on the maximal value. We used the resulting mode as the starting point for our MCMC sampling.

We then sample from the posterior distribution using a Metropolis-Hastings Markov chain Monte Carlo (MCMC) algorithm in order to make small sample inferences about the parameters. We sampled 10 separate chains for 45,000 periods each, discarding the first 15,000 periods. Thus we were left with 300,000 points from the posterior distribution. In order to assess convergence of the Markov chains, we use the potential scale reduction statistic described by Gelman, Carlin, Stern, and Rubin (2004) which gave clear indications of convergence for all the parameters.

C.3 Estimation Results for the Shocks and the Monetary Model

The text reports the estimation results for the structural parameters. Table 7 reports the estimates of the parameters for the shock processes. Figure 8 plots the prior and posterior distributions for the parameters describing the shock processes. Our prior insures that \( \sigma_r \) never hits zero, but its modal value is only \( 4 \times 10^{-6} \). Except for the investment shock, the AR(1) shocks are highly persistent, with the inflation objective shock in particular being nearly a unit root process.

Table 8 reports the estimates for the specification of the model with monetary frictions from Section 7.1.

D Optimal Policy

Here we report the impulse responses to other shocks.

In response to positive shocks to wages and Tobin’s Q, the optimal policy calls for a sharp increase in interest rates that causes a large decline in consumption. The contractionary policy response reduces the responses of wages. In contrast, the estimated policy rule accommodates the shocks to a greater degree and allows larger rises in wage inflation. The optimal policy response to a transitory shock to prices, however, is do virtually nothing. The estimated policy rule reacts to the rise in inflation, sending real rates higher and reducing consumption and aggregate labor.
